I propose a pipeline for summarizing scientific articles. The pipeline consists of a baseline algorithm, TextRank, to rank sentences within a document based on relevance of the words within each sentence. To improve the selection of important sentences, each ranked sentence is then given as input to an SVM classifier to decide whether the sentence should be included in the summary or not. The ROUGE results show an increase in the scores over the baseline and we also present an analysis of the why our algorithm performs better than the baseline.

# 1 Introduction

## 1.1 Problem Definition

A summary is a text that represents and preserves the important information conveyed by a document in a concise manner. Automatic summarization has been an area of research for the last couple of decades and has been tackled with different approaches. For my Final Year Project, I have decided to address the problem of summarization of scientific documents and put forward a solution in the form of a pipeline to process scientific articles and output their summaries.

In order to summarize a document, it is first necessary to identify what pieces of text within the document are important enough to represent the information conveyed by the document. Such pieces of text can range from single words (motivated by the problem of keyword extraction) to clauses and sentences within the document to be summarized. For this project, I will focus on complete sentences for the reason that a sentence represents a complete coherent line of thought compared to using clauses. So it would be easier to plug the chosen sentences into the summary without worrying about any significant loss of continuity.

Another point to be considered is that summaries are generally meant to be concise and limited in the number of words. It follows that not all information, that has been identified as important, might fit into a summary. Hence, there is a need to rank and choose the most important pieces of information (sentences) to be included into the summary.

Eventually, all the high ranked sentences are clubbed together and presented as a summary in what is termed as *extractive summarization*. A further improvement over creating extracts for summaries is to create an abstract of the assembled text which is a more recent and more difficult problem. However, in this study, I focus on creating extractive summaries.

To limit the domain of analysis, I decided to use scientific articles from the ACL Anthology.

## 1.2 Challenges with Summarization

Several summarization algorithms have been suggested in the past for creating extractive summaries. Some are simple algorithms like picking the first few lines of the article to be summarized or picking random sentences from the article. On the other hand, there are other algorithms that rank sentences based on the informative value of the content in the sentences.

The performance of such algorithms is judged based on the ROUGE score [C-Y Lin [9]]. ROUGE score for a summarization algorithm is calculated by comparing the summaries generated by this algorithm against gold standard summaries (human summaries)

for the corresponding articles. However, the interesting point is that each summarization algorithm has its advantages depending on the domain and the type of problem. For example, for summarization of news articles, directly picking the first few lines of the text has proven to be a strong baseline [Nenkova [13]]. Whereas for summarization of short articles, a rank based algorithm has been shown to perform much better than just picking the first few lines.

Considering that the corpus used for this project consists of scientific articles from the ACL Anthology, these articles are generally about a specific study and elaborate on the methodology of the conducted experiments, the results obtained, conclusion and possible discussion arising from conducting the experiments. These also include an "Introduction" section as well as a "Related Work" section to describe the work of others who have addressed the same or similar problem.

Prevalent summarization algorithms do not discriminate sentences on the basis of discourse. Hence their performance on scientific articles is expected to be low. This has been confirmed in this study as will be described in later sections.

## **1.3 Group Affiliation**

I performed this study under the supervision of Asoc. Prof. Min Yen Kan at the School of Computing, National University of Singapore. I am a member of a group of 5 individuals who are being advised by Prof. Kan and are working towards creating a Scientific Document Summarization System. The problem is inspired by the upcoming shared task which would involve a similar problem. My group is trying to tackle this problem from two perspectives. One is to look at the source document content to generate a summary. The other is to consider other scientific articles that cite the source article and analyse these citation sentences. This could be beneficial because such citation sentences generally describe the work done in the source article in a couple of lines.

I am responsible for preparing the system that analyses the source document content to generate an extractive summary.

## 2 Related Work

One of the earliest work done in summarization is that of Luhn [11] in which he used the frequency of words after stemming and removing stopwords. A significant factor for a sentence was derived from the number of occurrences of significant words (words with high frequency) and the distance between significant words in that sentence. The top ranked sentences based on this significance factor were selected to form the summary extract. Later features like sentence position (Baxendale [2]) and cue words (Edmundson [7]) were experimented with as well.

With the advent of NLP, researchers produced started to produce works with statistical learning. For example Aone et. al. [1] used term frequency and inverse document frequency as well as shallow discourse analysis (like reference to same entities in the text) to train a naive-Bayes classifier. Conroy and O’Leary [5] modeled the problem of extracting a sentence from a document using a hidden Markov model (HMM). The basic motivation for using a sequential model is to account for local dependencies between sentences. Only three features were used: position of the sentence in the document (built into the state structure of the HMM), number of terms in the sentence, and likeliness of the sentence terms given the document terms.

Score et. al. [8] propose an algorithm based on neural nets and the use of third party datasets to tackle the problem of extractive summarization, outperforming the baseline with statistical significance. They trained a model from the labels and the features for each sentence of an article, that could infer the proper ranking of sentences in a test document.

The work mentioned above involves training on corpus and hence is supervised. Un-supervised algorithms have also been proposed for this task. Mihalcea et al. [12] have proposed an algorithm, TextRank which is similar to PageRank [14]. TextRank is a graph based ranking algorithm which can be used to rank keyword phrases or sentences based on the content overlap with other sentences in the document. This has been further discussed later in the report.

Xie et al. [15] have discussed different metrics that could be used to calculate the importance of sentence content. They use such metrics to find the best set of sentences that could represent the entire document based on the content. The ranking algorithm used in this work calculates the Maximum Marginal Relevance [3] of sentences, which can be used as a score to rank sentences.

Lin et al. [10] have also proposed a graph based algorithm where the document is represented as a set of sentences ( $V$ ) in a graph with the edges defining the similarity between sentences. They define submodular functions using these similarity values to map a set of extracted sentences to a value that can quantify the efficiency of the summary. They use the greedy algorithm for this discrete optimization problem to incrementally add elements to the set that maximize the output. They report that this method outperforms MMR and TextRank methods. The summaries were created for meetings.

## 3 Methodology

### 3.1 Problem Description

Since this project is focussed on extractive summarization, the aim is to select sentences from the source article that could be considered worthy of being included in the summary. So I decided to approach this as a problem of classification of sentences (in the source document) into one of the two classes: 'belonging' to summary and 'not belonging' to summary.

### 3.2 Data Collection

Collecting a standard dataset for this task was not easy. There are no publicly available datasets consisting of scientific articles and their respective summaries. Hence, in order to build a dataset, articles were randomly sampled from the ACL Anthology. For the initial phase, 11 scientific articles were sampled to make up a small dataset to run the baseline on. This set of articles will be referred to as Data Set 1 in this report. For the second phase, 20 more articles from the same database were sampled. This set will be referred to as Data Set 2. Since the second phase involved experimentation with classification algorithms, this set of 20 documents (Data Set 2) was used for training and the set of 10 documents (Data Set 1) that was sampled earlier was used as the test set.

### 3.3 Evaluation Criteria

In accordance with the aim of the project, the evaluation of any system built should be based on the quality of summary produced by that system. Another constraint that was considered for this project was the length of the summary. It was decided that a summary should not exceed the length of 100 words. Being extractive in nature, the limit is imposed after discounting the stop words in the sentences.

For a quantitative judgment, the performance of both the baseline and further development over baseline is measured using ROUGE scores. ROUGE [9] is a summary evaluation system that measures the similarity of an automated summary with a set of reference summaries. Each automated summary can be evaluated against multiple reference summaries of the same text to get a better judgement about the automated summary.

For this project, a gold standard set was created to be used as reference summaries. The gold standard consisted of multiple summaries for each of the articles in Data Set 1. For each article, sentences that seemed most suitable for the summary of that article (based on human annotator judgement) were manually extracted until the aforementioned word limit was reached. This was done for each article in Data Set 1 by each annotator. The annotators consisted of all the members of the group that I worked with for this project.

In the second phase of the project, experiments done involved the classification of individual sentences into one of the two classes mentioned above. For this purpose, I extracted a set of sentences from each of the articles in Data Set 1. Then, I manually labelled these sentences into one of the two classes: -1, meaning the sentence is not suitable to be included in the ideal summary; or +1, meaning the sentence can be included in the ideal summary. The performance of using different features for classification of individual sentences was evaluated based on this labelled set of sentences.

## 3.4 Pre-Processing

Each document to be summarized is assumed to be provided in plain text of pdf format. To process this document, it is necessary to extract all the text as well as information about the document structure. This includes information about different sections in the document. This is done using the software package ParsCit/SectLabel that parses the document structure and citation sentences into well annotated and structure text.

## 3.5 Baseline

The first step was to build a basic system that could be the baseline for further experiments and improvements. Another factor for consideration was that the aim of the project was to create an extractive summary consisting of sentences from the same document that needs to be summarized. After studying various approaches used by researchers for single document summarization, I decided to use an unsupervised ranking algorithm. Following is a brief description of the TextRank algorithm, as introduced by [?], to explain how a graph based ranking algorithm can be applied to rank sentences within a document.

### 3.5.1 TextRank

The basic idea implemented by a graph-based ranking model is that of 'voting' or 'recommendation'. When one vertex links to another one, it is basically casting a vote for the other vertex. The importance of a vertex is based on the number of votes casted towards that vertex.

Formally, let  $G = (V, E)$  be a directed graph with the set of vertices  $V$  and set of edges  $E$  where  $E$  is a subset of  $V \times V$ . For a given vertex  $V_i$ , let  $In(V_i)$  be the set of vertices that point to it, and let  $Out(V_i)$  be the set of vertices that  $V_i$  points to. The score of vertex  $V_i$  is defined as follows (Brin and Page [1]),

$$S(V_i) = (1 - d) + d * \sum_{j \in In(V_i)} \frac{1}{|Out(V_j)|} S(V_j)$$

where  $d$  is the damping factor that can be set between 0 and 1. The factor  $d$  is generally set to 0.85 and this the value that was used for my experiments as well. Starting with arbitrary values assigned to each node in the graph, the computation iterates until convergence below a given threshold is achieved. The final score associated with each vertex represents the *importance* of that vertex within the graph.

Two modifications were introduced by Mihalcea [12] to apply this algorithm to documents for ranking sentences. The first modification was to define the above mentioned algorithm for undirected graphs in which case, the out-degree of the vertex is equal to the in-degree of the vertex. The other modification was to incorporate the notion of *strength* of the connection between any two vertices as a weight  $w_{ij}$  added to the corresponding edge that connects the two vertices. Consequently, the new formula that takes into account these two modifications and gives the weighted score is

$$WS(V_i) = (1 - d) + d * \sum_{V_j \in In(V_i)} \frac{w_{ji}}{\sum_{V_k \in Out(V_j)} w_{jk}} WS(V_j)$$

### 3.5.2 TextRank for Summarization

To apply this algorithm for ranking sentences, a graph is built in which the sentences (from the source document) represent the vertices of the graph, and the edges between these vertices is defined by the sentence 'similarity'. Here, 'similarity' is a measure of the content overlap between the two sentences that connected by that edge. This overlap of content between any two sentences can be defined by the number of common tokens between the lexical representations of the two sentences.

For the purpose of the work described in thesis, this concept of similarity between sentences within a document has been implemented in the following way. A matrix of *tf-isf* (term frequency - inverse sentence frequency) is constructed for the entire document. This *tf-isf* matrix is then multiplied by its transpose to obtain the similarity matrix with dimensions equal to the number of sentences in the entire document, and each value representing the similarity between the two sentences used to index that value in the matrix.

After running the ranking algorithm over this graph until convergence, the sentences are sorted in decreasing order based on the final score. The top ranked sentences are selected for inclusion in the summary. The performance of this algorithm on scientific articles is documented in detail in the Results section of this report. This is chosen as the baseline as it has been shown to perform reasonably well on unstructured text, for example news articles.

Although the performance of the baseline system was decent, further qualitative analysis of the summaries generated by this baseline showed that these summaries included sentences which varied in degree of suitability to be included in the ideal summary. Here ideal summary would be one that is similar in content to the summary created by humans as in the gold standard that is used in this project. Each of the extracted sentence from this baseline was objectively judged as to whether its contents were important enough for that sentence to be included in the ideal summary. It was found that 30% of all the extracted sentences were not suitable in this respect.

Figure 3.1 and 3.2 show two summaries generated by the baseline where the highlighted sentences are the ones that are not suitable to be included in the summary. It can be seen that these sentences are either citation sentences or those that are extremely specific in context to the experiments described.

The evaluation of baseline helped in understanding that it is not enough to rely on an algorithm that ranks sentences based on content overlap with other sentences. The

The motivation for this paper is to discover which joining terms are good predictors of a semantic relation, and which learning algorithms perform best at the task of mapping from joining terms to semantic relations for modifier-noun compounds. Also, they use 64 joining terms and gather counts for both the forms 'noun joining term modifier' and 'modifier joining term noun' (128 frequencies in total); while we use only the former construction with 28 joining terms. Turney and Littman (2005) use a set of 64 short prepositional and conjunctive phrases they call 'joining terms' to generate exact queries for AltaVista of the form 'noun joining term modifier', and 'modifier joining term noun'.

Figure 3.1: Summary generated by the baseline

Moore and Pollack (1992) propose that, in fact, two contiguous spans of text may be in both an informational and an intentional relation simultaneously and that recognition of one kind of relation can facilitate recognition of the other. As noted above, nuclearity, which was an element of the unique RST relation between spans N and 5, is now an element, of the intentional relation and is independent of the informational relation. In its broadest outline, the goal is to understand the precise interaction between features of form, meaning and function in the creation of discourse coherence. By investigating the range of combinations of informational and intentional relations which occur with a lexical marker, we can identify the minimal description of the marker in terms of discourse relations.

Figure 3.2: Summary generated by the baseline

importance of the words within the sentence should also be considered. I decided to explore how the importance of words appearing in a sentence, with respect to the article being summarized, relates to whether that sentence should be included in the summary or not. It is also important to limit the examination to words that contribute to the immediate (central) meaning conveyed by the sentence as opposed to considering adjunct clauses or phrases that do not contribute much to the central meaning of the sentence. The following sections, I have documented the different experiments tried out to this end.

## 3.6 Data Preparation

Before explaining the different experiments tried, I would like to explain the preparation of training and test sets for the second phase of the project. As mentioned earlier, data collection was a difficult process as there is no publicly available data for such a task. In Section 3.2, I have mentioned that two data sets were prepared, Data Set 1 and Data Set 2. Scientific articles in Data Set 1 were used in the first phase (described above) to extract sentences to form summaries and then the ROUGE score of the baseline summarizer was calculated by comparing the generated summaries against the gold standard summaries.

In Section 3.3, I have mentioned that articles in Data Set 1 were further processed to get labelled sentences. This was done in the following manner. For each article in Data Set 1, all the sentences were ranked using TextRank and the top 7 sentences were chosen. These 7 sentences were manually labelled as belonging to either class -1 or class +1. The rationale behind using TextRank for such sampling is that this ranking algorithm is the baseline. Being the baseline, it will be used in the pipeline of the final system after the preprocessing step. So the input to the classification algorithm would come from this baseline module. Hence, to create a test set of labelled sentences to evaluate the performance of the classification module, I decided to use the top 7 sentences ranked by the baseline, from each of the article in Data Set 1. Since Data Set 1 consisted of 11 articles, there were 77 labelled samples in the test set of which 33 were positive and 44 were negative samples.

For the training set, Data Set 2 was used, which consisted of 20 articles. Since it is not

easy to manually label sentences in each document into the desired classes, I applied an approximation. This is based on the fact that the abstract of a scientific article represents the information that has to be included in the summary. So I decided to consider all the sentences in the abstracts of all the articles in Data Set 2 to be positive samples for classification.

For negative sample collection, for each article in Data Set 2, I ranked all the sentences using TextRank and chose the lowest ranked sentences. I made the assumption that if a sentence is ranked low by TextRank, then it is not suitable to be included in the summary and can be considered a negative sample. In the previous section, I argued that a high degree of content overlap of a sentence with other sentences in the document is not definitively indicative of its importance with respect to the document. However, if this degree of content overlap is very low, it indicates that the content in that sentence is either too specific to have appeared often in the document, or the content is irrelevant with respect to the main topic of the entire document. In either case, such a sentence can be considered as a negative sample. There were 183 samples in the training set of which 83 samples were positive and 100 were negative. A small point to be noted is that while sampling these negative sentences, I eliminated sentences which can not be considered valid sentences. This validity is defined by sentence length (between 15 to 40 words was considered valid) and presence of non-alphanumeric characters.

### 3.7 Dependency Parses

A dependency parse of a sentence represents the grammatical relationships of words in that sentence. It is different from a constituent parse of a sentence. While a constituent parse breaks a sentence into different phrases down to the individual words (commonly known as phrase structure representation), a dependency parse is used to represent the textual relationships between words in that sentence. Depending on the language as well as the purpose of the analysis, different dependency grammar conventions can be used.

For this project, I decided to follow Stanford Typed Dependency relations. In this kind of dependency parse, each word is associated with another word and this association is defined by a dependency relation. There are around 50 grammatical relations (dependencies) defined for Stanford Type Dependency Parser. Consider the following example:

*Bills on ports and immigration were submitted by Senator Brownback, Republican of Kansas*

For the above sentence, the Stanford Types Dependencies as well as a graphical representation of this dependency parse is shown in Figure 3.3.

It can be seen that this kind of dependency parse helps in identifying the latent relationships between different words in a sentence.

As described in the previous section, the baseline uses the textual content overlap of a sentence with others in the document to decide how important the sentence within that document. The baseline algorithm does not have the ability to process information beyond the textual content in a sentence. Therefore, I decided to use dependency parse of sentences to extract information that could be used as features to classify each sentence into one of the classes defined earlier (-1 or +1).

In the following sections, I describe my experiments in extracting useful features from

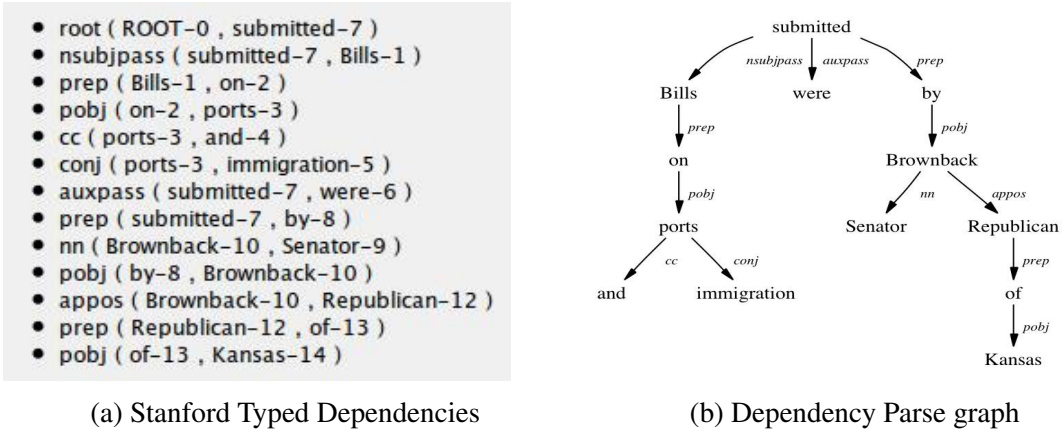

Figure 3.3: Stanford Dependency Parse

dependency parse trees for this purpose.

## 3.8 Convolution Kernels

Kernel methods are one of the popular pattern recognition algorithms that use kernel functions to map high dimensional data points to an inner product space in order to apply linear classification in this new space. Support Vector Machines is a well know kernel method that is used for pattern classification classification. Depending on the nature of data, SVM can be used with different types of kernels such as linear, polinomial, radial basis function and many others. For example, with numerical data, using a liner kernel will map high dimansional data points into a feature space, where only the distance between the projections of data points over a certain line (defined by the kernel) will be used for drawing margins for classification.

In this report, I discuss the use of Convolution kernel (Collins and Duffy [4]), which is a type of string kernel that makes use of the structural information within a sentence. Convolution kernels use the sentence tree structures and calculate the similarity between two trees. This is done by recursively counting the number of identical sub-trees that appear in both input trees.

Hence, convolution kernles can help in providing a mapping between the sentences and their structural similarity with other sentences.

Moschitti et. al.[6] describe an efficient algorithm for using convolution kernel as the kernel function for SVM. They have used the SVM-light library and included a new kernel definition for efficient computation of convolution kernel, SVM-light-TK. This library can take any kind of parse tree as input.

### 3.8.1 Experiment

I decided to use SVM-light-TK for classification of sentences. Each sentence was first passed through the Stanford Parser and the dependency parse tree for the sentence was obtained. Each node in the parse tree consisted of 3 components : the actual word on that

node, the part of speech tag of that word and its dependency relation with its parent node. This representation for the following sentence has been shown in Figure 3.4.

*The user could ask it to build up a computer configuration satisfying his particular needs.*

```

ask-VB (root)
  user-NN (nsubj)
  The-DT (det)
  could-MD (aux)
  build-VB (xcomp)
  it-PRP (nsubj)
  to-TO (aux)
  up-RP (prt)
  configuration-NN (dobj)
  a-DT (det)
  computer-NN (nn)
  satisfying-VBG (partmod)
  needs-NNS (dobj)
  his-PRP$ (poss)
  particular-JJ (amod)

```

Figure 3.4: Dependency Parse representation from Stanford Parser

SVM-light-TK has the provision of specifying more than one tree structure as the feature vector for each sentence (sample). So, I separated each component of each node and created feature vector containing three trees. The first tree consisted of the words. The second tree consisted of the nodes in the same position, but only the part of speech tags of the words were used. Similarly, the third tree contained only the dependency relations of each node to its parent.

The classification was done over the training set and the model was tested over the test set as mentioned in the section on Data Preparation.

### 3.8.2 Results

Following is the result of using convolution kernels to train SVM over the training sentences. The confusion matrix of the model tested over the test set is shown in Table 3.1

Table 3.1: Confusion matrix for the evaluation of SVM using convolution kernel over test set

		Predicted Class	
		Positive	Negative
Actual Class	Positive	12	21
	Negative	20	24
Precision		37.5%	
Recall		36.36%	

It can be seen that the values of both Precision and Recall of the model over the test set are very low.

### 3.8.3 Discussion

The poor performance of the classifier using convolution kernel can be explained by considering the inherent nature of convolution kernels. Convolution kernels are used to classify sentences on the basis of structural differences (or similarities). As explained earlier, they work on the principle of finding similar structures of sub-trees between two trees. However, for the task at hand, sentences have to be classified on the basis of how similar the content is to the main topic being discussed in the article. In that respect, the structure of a sentence and the variability in the dependency relations of words within that sentence do not provide any indication about the importance of the content in that sentence.

The above experiment and analysis helped in the realization that for classification of sentences into the desired classes, the content of a sentence has to be examined closely for better feature extraction.

## 3.9 Importance Features

I decided to concentrate on the different parts of a dependency tree. There are three important grammatical components in a dependency parse of a sentence that I decided to look into : *verb*, *subject* and *object*. It can be seen from the dependency parse representation that the main *verb* in the sentence is the *root* of the parse. In accordance with the rules of English grammar, the main verb is associated with either a subject or an object or both a subject and an object. This can be noticed in the dependency parse as well. Consider the dependency parse shown in Figure 3.2. The subject in the sentence is 'user' and its dependency relation to the main verb 'ask' is 'nsubj' which means *nominal subject*. Similarly, there is an object in the sentence, 'configuration' which is related to the verb 'build' (which is not the main verb in the sentence) by the relation 'dobj' which means *direct object*.

It was my hypothesis that these three dependency relations can be helpful in identifying phrases containing words that should be examined for importance. By importance, I mean the degree of closeness of these words to the main topic of discussion in an article. This importance can be measured using various text-based metrics used in Information Retrieval and Text Processing such as the total count of occurrence of words, their term frequency inverse document frequency (tf-idf) and term frequency inverse sentence frequency (tf-isf).

Stanford Typed Dependencies [...] define the relation between a verb and the subject attached to it using different dependency relations depending on the context. These are *csubj*, *csubjpass*, *nsubj*, *nsubjpass* and *xsubj*. Similarly, the dependency relation between a verb and the attached object is defined by *dobj*, *iobj* and *pobj*. For this experiment, I did not consider the different types of subject and object dependencies as I was only interested in finding the subjects and objects irrespective of the context with the verb.

### 3.9.1 Experiment

For each sentence, its dependency parse tree is first obtained. Since the verb is the root of the tree, it can be easily accessed. The algorithm then searches for both subject (the

letters 'subj' in the dependency relation) and object (the letters 'obj') in the dependency tree. The search for subject and object in the tree is Breadth-First Search in order to find the subject and object as high up in the tree as possible. This is done because a sentence might contain multiple subjects or objects. In such a case, it is important to pick up the subject (or object) that is closer to the main verb of the sentence. After obtaining these three nodes, verb, subject and object, the importance of these nodes is to be calculated using the metrics mentioned above.

For the subject node, all the nodes in the sub-tree with the subject as the root are also considered for the calculation of importance. The same is true for the object node as well. This is done because I wanted to capture the importance of the entire phrase associated with the subject and the object.

## Metrics

For this task, the corpus consists of documents that have to be individually summarized. This means that the system obtained from this effort needs to take a single document as input and produce its summary without the context of any other document. The purpose of using a corpus of documents for this task is to collect statistics over multiple documents rather than treating the corpus as a controlled set. Hence, I decided to exclude the computation of term frequency inverse document frequency (tf-idf) of words within a document with respect to the entire corpus.

The metrics that I used in experiments for the computation of 'importance' of verb, subject phrase and object phrase in each sentence are : *count*, *term frequency inverse sentence frequency (tf-isf)*, and *term frequency inverse section frequency (sec-tf-idf)*.

Count represents the count of the word being considered throughout the entire document. The tf-isf is calculated in the same way as term frequency inverse document frequency is calculated. The only difference is that for tf-isf, the sentence containing that word is considered the 'document' and the entire article (document containing the sentence) is treated as the corpus. The sec-tf-idf is also calculated in a similar way as tf-idf. Except that in this case, the section in which that word occurs is treated as the 'document' and the entire article is treated as the corpus. The information about the section is obtained from the preprocessing step from the annotations of the output from the software package ParsCit/SectLabel.

The last metric is a novel metric proposed by me in this study.

## Feature Extraction

For the verb node, the calculation of the features is straight-forward. The three metrics are obtained for the word representing the verb node. For subject phrase, the tf-isf of each word (node) in the subtree (with the subject node as the root) is calculated. If the word is a stop-word, then the tf-isf value for that node is assigned as 0. Once the tf-isf values of all the words in the subject phrase have been obtained, the average of these values is computed. This average value is used as the tf-isf value of the subject phrase. The values of count and sec-tf-idf are also calculated in the same way. Also, the same process is followed for calculating these metrics for the object phrase.

A point to be noted is that the list of stop-words was modified. All first-person and third-person pronouns were removed from the stop-word list. The reason behind this

is that, considering the domain of the task, it is common to find sentences in scientific articles that contain the word 'we'. Such sentences generally describe the work done by the authors of the article and most probably the work done in the same study that the article is about. Likewise, it is common to find sentences that contain the word 'they' and such sentences generally point to work done by other researchers that are cited by the authors of the article. Hence, these words can not be ignored.

Once these features are obtained, the training set is used to train an SVM classifier with RBF kernel. I tried different combinations of features and tuning parameters which are listed below.

- The count, tf-idf and sec-tf-idf features were considered separately.
- The three metrics were considered together.
- The *gamma* value for the SVM classifier was varied from 0.001 to 100
- For calculation of the metric over the sub-tree, for every descent to a lower level in the tree, the value of the metric at that level is multiplied by a constantly decaying factor. This factor was reduced by a constant degree with each level ranging from 0.5 to 2. This was done to reduce the effect of lower values of nodes in the sub-tree that could be responsible for reducing the value of the entire phrase.

Section 4 documents the results obtained from these experiments.

## 3.10 Final Pipeline

The final pipeline is constructed of the following components:

1. Preprocessing module : as described in Section 3.4
2. Baseline module : TextRank algorithm.
3. Classification module : Using the importance feature sec-tf-idf to train SVM.

An input document, after being preprocessed, is passed to the baseline module. The baseline module uses TextRank to rank all the sentences in the document. Then starting from the highest ranked sentence, each sentence is passed to the classification module. Here the dependency parse of the sentence is obtained and then the sec-tf-idf values of the verb, subject phrase and object phrase are computed. These values are used as features and the feature vector is used to classify that sentences using the trained model. If the class is predicted as '1', then the sentence is selected to be included in the summary. This process is repeated for each sentence until the word limit of the summary is reached.

In the event that even after processing the top 20 sentences from the baseline module, the summary length has not reached the limit, the top 20 sentences are considered again. Of these 20 sentences, apart from the ones that have already been included in the summary, the sentences are ranked again based on the prediction value of the SVM classifier for the corresponding sentences. The top ranked sentences are then included in the summary until the limit is reached.

This process is carried out for all the sentences in Data Set 1. The summaries produced are then compared against the gold standard using ROUGE scores. The results have been documented in Section 4.

## 4 Results

This section documents the results obtained from the baseline as well as the experiments conducted using the importance features to train SVM classifier as describe in Section 3.9. The reuslts of comparision of the performance of the final pipeline with the gold standard have also been documented here.

Table 4.1 shows the ROUGE scores obtained by comparing the baseline (TextRank) algorithm with the gold standard summaries. It also shows the ROUGE scores of comapring the summaries generated by the final pipeline with the gold standard summaries.

Table 4.1: ROUGE unigram scores

ROUGE (unigram)	TextRank	Final Pipeline
Recall	0.447	0.536
Precision	0.452	0.466
F-measure	0.449	0.493

The classification results of using the importance features for training SVM are as follows.

- When I tried to train SVM classifier using tf-idf values, the model was extremely poor. Even on the training set, the classifier was not able to classify any of the positive samples correctly.
- Using count as the metric resulted in a similar model. This time, not all positive samples were misclassified. But 90% of the positive samples were misclassified. Although, it is worth mentioning that the values of all the misclassified positive samples were close to 0.0 margin.
- Using sec-tf-idf resulted in a better trained SVM model. The precision and recall on the training set was 0.85 and .963 respectively. The confusion matrix for the evaluation of this model over the test set is given in Table 4.2.

Table 4.2: Confusion matrix for trained model using sec-tf-idf on test set

		Predicted Class	
		Positive	Negative
Actual Class	Positive	8	25
	Negative	3	41
Precision		72.73%	
Recall		24.24%	

The plots of the three features have been shown in Figure 4.1. Here, 'red' represents positive samples and 'blue' represents negative samples. The *circle* represents correctly classified sentences and *triangle* represents incorrectly classified sentences.

(a) Object - Subject Plot

(b) Verb - Object Plot

(c) Verb - Subject Plot

Figure 4.1: Feature Plots

- The model trained using both count and sec-tf-idf values was as poor as the model trained using just the counts.
- Varying the *gamma* value for the RBF kernel did not show a drastic change in the overall performance of the classifier. Table 4.3 shows the difference in the precision and recall on the test set as the gamma value was changed.

Table 4.3: Change in Precision and Recall on the test set on varying gamma

gamma	Precision	Recall
0.01	0.692	0.272
0.1	0.692	0.272
1.0	0.692	0.272
10	0.81	0.27
100	0.81	0.27

- Varying the decaying factor for calculation of sec-tf-idf value did not show any drastic change in the performance. Table 4.4 shows the values of precision and recall on the test set as the decaying factor is changed.

Table 4.4: Change in Precision and Recall on varying the decay factor

Decay	Precision	Recall
0.2	0.777	0.212
0.5	0.8	0.24
1.0	0.692	0.272
1.5	0.769	0.303

Although the test set was small in size, the sentences in this set were manually labelled unlike the sentences in the training set whose labels were approximated. So in order to validate the performance of this model, I decided to use the test set for k-fold validation. The results of such validation can be extrapolated to estimate the performance of this model over a larger data set. With 11 sentences in each set, I conducted a 7-fold validation. The average values of precision was 0.81 and recall was 0.35. This is slightly better than the performance of the model over the entire test set and can be attributed to the small size of the data set. However, this also shows that the validation result was close to the test set evaluation and hence the model is expected to perform similarly with larger training and test sets.

## 5 Discussion

From the results in the previous section, it can be seen that the performance of the Classifier module over the test set was better than the performance of the baseline. It shows that considering such features that rely on computation of relevance of the content within a sentence can give much better results than considering just the textual content of the sentence. This can be attributed to the fact that in the Classification module, the features extracted for classification of the sentence captured the relevance of the the words (that appear in that sentence) with respect to the entire document.

Although the test set consisted of sentences that were all selected from the top of the output of the TextRank algorithm, the negative sentences in the training set were picked from the bottom of the output of the TextRank algorithm. From the confusion matrix in Table 4.2 we can see that the negative predictive value (which indicates how well negative samples are classified) of the trained model is 62.2% and the specificity (which indicates the fraction of true negative samples that were identified correctly) is 93.1%. This shows that the trained model is able to identify the negative sentences in most of the cases. This helps in validating the decision to pick negative samples as the the lowest ranked sentences in the document for training.

Despite the accuracy of the trained model in predicting negative sentences, it is still more important to judge the classifier based on its efficiency to classify positive sentences correctly. This is because the aim of the task is to highlight sentences that could be important, which are positive sentences in the data set. A close analysis of the sentences in the test set, their respective feature values and the real and predicted classes for each helped in understanding the shortcomings of the model. Since the importance metric  $\text{sec-tf-idf}$  is calculated by considering the section (as annotated in the document structure) as a document and the whole document as the corpus, the value of the same word differs with its occurrence in different sections.

Figure 5.1 shows the dependency parse of a positive sentence which was classified correctly by the trained model. The values of the three features have also been mentioned beside the words that represent the subject, the verb and the object phrases. Although it is an estimate in accordance with the plots shown in Figure 4.1, it can be seen that these values are high enough to be considered as positive samples.

Figure 5.2 shows the dependency parse of another positive sample which was classified incorrectly by the trained model as a negative sentence. Here it can be seen that the value of the word 'propose' is 0.007 which is quite low where as the value of the same word in Figure 7.1 is 0.08. The values of this word are different because the two sentences appear in different sections.

I used the value of the word 'propose' from the first sentence as a feature for the second sentence since in both the sentences this word is the main verb and is used for that feature. With this and the other two values of subject and object phrases from the second sentence, I created a feature vector and used the trained model to classify it. The

(b) A false positive sentence

feature vector was classified as a positive sample.

From the above discussion it can be seen that although the feature sec-tf-idf can be used to perform classification that could lead to improvement over the baseline, it can still miss out on positive sentences. Although the precision of the train model using this novel metric is sufficiently good, the recall is poor. For summarization, it is important to find sentences that could be included in the summary. Hence, there is a need to improve the features to help better map the importance of words in a sentence.

A further improvement that has been proposed for future work is to add a linear component to the features being calculated. a feature that measure a more general significance of words can be used. This can be measure over large corpus which need not necessarily be a collection of scientific articles. A possible suggestion is the use of Google n-gram data set. The feature could be a linear combination of the sec-tf-idf value as well as Google n-gram data set.

## 6 Conclusion

In this report, I documented the research conducted by me along with my group to develop a pipeline for summarizing scientific articles. The baseline was built using TextRank algorithm which is unsupervised and hence produces a output in the form of ranked sentences based on content overlap between sentences. This output can be used for further processing.

Experiments were conducted to build a classification model that can identify the importance of sentences within a document. Different metrics were tried as features for the words and phrases representing the verb, subject and object of a sentence. A novel metric was proposed which measure the importance of words with respect to the section that the sentence appears in. The classification model build using this feature set was seen to perform better than the baseline. The final pipeline was used to create summaries which were judged against gold standard and it performed better than the baseline.

An in depth analysis of this approach helped in understanding the strength and weakness of the feature set and the values. This has helped in planning for the next phase in terms of deciding the improvements to be done to the features in the next iteration of experiments.
